Chemistry Grade 11 General EoT1 2025-2026 revision

Bohr's Model of the Atom

The dual wave-particle model of light accounted for several previously unexplainable phenomena, but scientists still did not understand the relationships among atomic structure, electrons, and atomic emission spectra. Recall that hydrogen's atomic emission spectrum is discontinuous; that is, it is made up of only certain frequencies of light. Why are the atomic emission spectra of elements discontinuous rather than continuous? Niels Bohr, a Danish physicist working in Rutherford's laboratory in 1913, proposed a quantum model for the hydrogen atom that seemed to answer this question. Bohr's model also correctly predicted the frequencies of the lines in hydrogen's atomic emission spectrum.

Energy states of hydrogen

Building on Planck's and
Einstein's concepts of quantized
energy, Bohr proposed that the
hydrogen atom has only certain
allowable energy states, as
illustrated in Figure 10. The lowest
allowable energy state of an atom
is called its ground state. When an
atom gains energy, it is said to be
in an excited state.

Bohr suggested that the electron in a hydrogen atom moves around the nucleus in only certain allowed circular orbits. The smaller the electron's orbit, the lower the atom's energy state, or energy level. Conversely, the larger the electron's orbit, the higher the atom's energy state, or energy level. Bohr assigned a number, n, called a quantum number, to each orbit. He also calculated the radius of each orbit. Table 1 shows data for the first seven energy levels of a hydrogen atom according to Bohr's model.

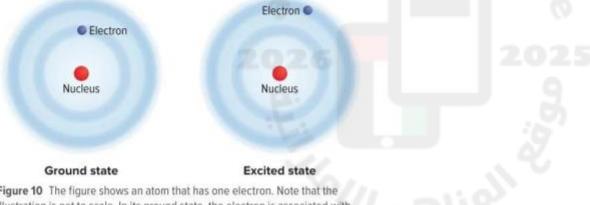

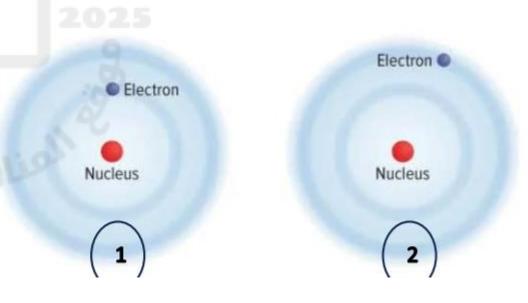

Figure 10 The figure shows an atom that has one electron. Note that the illustration is not to scale. In its ground state, the electron is associated with the lowest energy level. When the atom is in an excited state, the electron is associated with a higher energy level.

What is called the state of the atom when it gains energy according to Bohr's model?	ماذا تمسى الحالة التي تكون الذرة فيها عندما تكتسب طاقة وفق نموذج بور؟
A. Ground state	 الحالة الأرضية
B. Excited state	B. الحالة المستثارة
C. Inert state	 الحالة الخاملة
D. Radiation-emitting state	D. حالة انبعاث الاشعاع

4- Regarding the atom structure on the right

- a) Figure 2 represents lowest allowable energy state
- b) Figure 2 represents excited energy state
- c) The atoms gain energy to reach figure 1
- d) The atoms lose energy to reach figure 2

Principal quantum number

Recall that the Bohr atomic model assigns quantum numbers to electron orbits. Similarly, the quantum mechanical model assigns four quantum numbers to atomic orbitals. The first one is the **principal quantum number** (n) and indicates the relative size and energy of atomic orbitals. As n increases, the orbital becomes larger, the electron spends more time farther from the nucleus, and the atom's energy increases. Therefore, n specifies the atom's major energy levels. Each major energy level is called a **principal energy level**. An atom's lowest principal energy level is assigned a principal quantum number of 1. When the hydrogen atom's single electron occupies an orbital with n = 1, the atom is in its ground state. Up to 7 energy levels have been detected for the hydrogen atom, giving n values ranging from 1 to 7.

Energy sublevels

Principal energy levels contain **energy sublevels.** Principal energy level 1 consists of a single sublevel, principal energy level 2 consists of two sublevels, principal energy level 3 consists of three sublevels, and so on. To better understand the relationship between the atom's energy levels and sublevels, picture the seats in a wedge-shaped section of a theater, as shown in **Figure 16**. As you move away from the stage, the rows become higher and contain more seats. Similarly, the number of energy sublevels in a principal energy level increases as *n* increases.

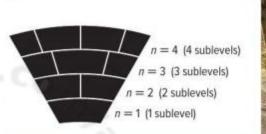

Figure 16 Energy levels can be thought of as rows of seats in a theater. The rows that are higher up and farther from the stage contain more seats. Similarly, energy levels related to orbitals farther from the nucleus contain more sublevels.

Table 2 Hydrogen's First Four Principal Energy Levels

Principal Quantum Number (n)	Sublevels (Types of Orbitals) Present	Number of Orbitals Related to Sublevel	Total Number of Orbitals Related to Principal Energy Level (n²)
1	s	1	1
2	s p	1 3	4
3	s p d	1 3 5	9
4	s p d f	1 3 5 7	16

Hydrogen's first four principal energy levels, sublevels, and related atomic orbitals are summarized in **Table 2**. Note that the number of orbitals related to each sublevel is always an odd number, and that the maximum number of orbitals related to each principal energy level equals n^2 .

Which of the following statements is correct?

أي العبارات التالية صحيحة؟

Principal energy level 3 consists of three

sublevels, they are 3s, 3p and 3f

Principal energy level 3 consists of three

Ground-State Electron Configuration

The arrangement of electrons in an atom is called the atom's **electron configuration**. Because low-energy systems are more stable than high-energy systems, electrons in an atom tend to assume the arrangement that gives the atom the lowest energy possible. The most stable, lowest-energy arrangement of the electrons is called the element's ground-state electron configuration.

Three rules, or principles—the aufbau principle, the Pauli exclusion principle, and Hund's rule—define how electrons can be arranged in an atom's orbitals.

The aufbau principle

The aufbau principle states that each electron occupies the lowest energy orbital available. Therefore, your first step in determining an element's ground-state electron configuration is learning the sequence of atomic orbitals from lowest energy to highest energy. This sequence, known as an aufbau diagram, is shown in Figure 18. In the diagram, each box represents an atomic orbital.

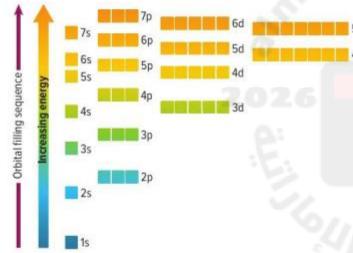

Figure 18 The aufbau diagram shows the energy of each sublevel relative to the energy of other sublevels.

Determine Which sublevel has the greater energy, 4d or 5p?

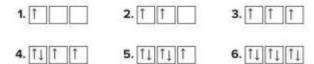

The Pauli exclusion principle

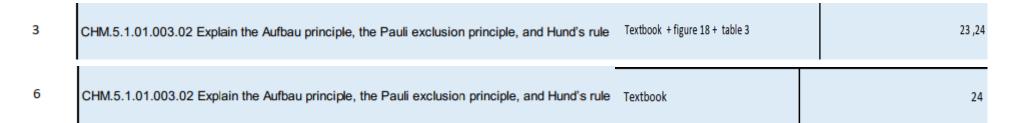

Every electron has an associated spin, similar to the way a top spins on its point. Like a top, an electron is able to spin in only one of two directions. The **Pauli exclusion principle**, proposed by Austrian physicist Wolfgang Pauli (1900–1958), states that a maximum of two electrons can occupy a single atomic orbital, but only if the electrons have opposite spins.

Electrons in orbitals can be represented by arrows in boxes. An arrow pointing up represents the electron spinning in one direction, and an arrow pointing down represents the electron spinning in the opposite direction. An empty box represents an unoccupied orbital, a box containing a single up arrow represents an orbital with one electron, and a box containing both up and down arrows represents a filled orbital containing a pair of electrons with opposite spins.

Hund's rule

The fact that negatively charged electrons repel each other affects the distribution of electrons in equal-energy orbitals. **Hund's rule** states that single electrons with the same spin must occupy each equal-energy orbital before additional electrons with opposite spins can occupy the same orbitals. For example, the boxes below show the sequence in which six electrons occupy the three 2p orbitals. One electron enters each of the orbitals before a second electron enters any of the orbitals.

Which of the following is correct?

Electron Arrangement

You can represent an atom's electron configuration using one of two convenient methods: orbital diagrams or electron configuration notation.

Orbital diagrams

As mentioned earlier, electrons in orbitals can be represented by arrows in boxes. Each box is labeled with the principal quantum number and sublevel associated with the orbital. For example, the orbital diagram for a ground-state carbon atom, shown below, contains two electrons in the 1s orbital, two electrons in the 2s orbital, and one electron in two of three separate 2p orbitals. The third 2p orbital remains unoccupied.

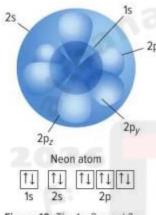

Figure 19 The 1s, 2s, and 2p orbitals of a neon atom overlap.

Determine how many electrons a neon atom has.

Electron configuration notation

The electron configuration notation designates the principal energy level and energy sublevel associated with each of the atom's orbitals and includes a superscript representing the number of electrons in the orbital. For example, the electron configuration notation of a ground-state carbon atom is written 1s²2s²2p².

Orbital diagrams and electron configuration notations for the elements in periods one and two of the periodic table are shown in **Table 4. Figure 19** illustrates how the 1s, 2s, $2p_{sr}$, $2p_{sr}$, and $2p_z$ orbitals illustrated earlier in **Figure 17** overlap in the neon atom.

Table 4 Electron Configurations and Orbital Diagrams for Elements 1–10

Element	Atomic Number	Orbital Diagram 1s 2s 2p _x 2p _y 2p _z	Electron Configuration Notation
Hydrogen	1	<u>↑</u>	1s¹

Fluorine	9	tt tt tt	1s² 2s² 2p ⁵
Neon	10	T1 T1 T1 T1	1s² 2s² 2p6

Noble-gas notation Noble gases are the elements in the last column of the periodic table. Their outermost energy levels are full, and they are unusually stable. Noble-gas notation uses bracketed symbols to represent the electron configurations of noble gases. For example, [He] represents the electron configuration for helium, 1s², and [Ne] represents the electron configuration for neon, 1s²2s²2p6.

Compare the electron configuration for neon with sodium's configuration above. Note that the inner-level configuration for sodium is identical to the electron configuration for neon. Using noble-gas notation, sodium's electron configuration can be shortened to the form [Ne]3s1. The electron configuration for an element can be represented using the noble-gas notation for the noble gas in the previous period and the electron configuration for the additional orbitals being filled. The complete and abbrevi-

Table 5 Electron Configurations for Elements 11-18

Valence Electrons

5

Only certain electrons, called valence electrons, determine the chemical properties of an element. Valence electrons are defined as electrons in the atom's outermost orbitals—generally those orbitals associated with the atom's highest principal energy level. For example, a sulfur atom contains 16 electrons, only six of which occupy the outermost 3s and 3p orbitals, as shown by sulfur's electron configuration, [Ne]3s²3p⁴. Sulfur has six valence electrons. Similarly, although a cesium atom has 55 electrons, it has just one valence electron, the 6s electron shown in cesium's electron configuration, [Xe]6s¹.

Electron-dot structures

Because valence electrons are involved in forming chemical bonds, chemists often

represent them visually using a simple shorthand method, called electron-dot structure. An atom's electron-dot structure consists of the element's symbol, which represents the atomic nucleus and inner-level electrons, surrounded by dots representing all of the atom's valence electrons. In writing an atom's electron-dot structure, dots representing valence electrons are placed one at a time on the four sides of the symbol (they may be placed in any sequence) and then paired up until all are shown. Table 6 shows examples for the second period.

Table 6 Electron Configurations and Dot Structures

Element	Atomic Number	Electron	Electron-Dot Structure

EXAMPLE Problem 3

ELECTRON-DOT STRUCTURES Some toothpastes contain stannous fluoride, a compound of tin and fluorine. What is tin's electron-dot structure?

1 ANALYZE THE PROBLEM

Consult the periodic table to determine the total number of electrons in a tin atom. Write out tin's electron configuration, and determine its number of valence electrons. Then use the rules for electron-dot structures to draw the electron-dot structure for tin.

2 SOLVE FOR THE UNKNOWN

Tin has an atomic number of 50. Thus, a tin atom has 50 electrons.

[Kr]5s24d105p2

Write out tin's electron configuration using noblegas notation. The closest noble gas is Kr.

The two 5s and the two 5p electrons (the electrons in the orbitals related to the atom's highest principal energy level) represent tin's four valence electrons. Draw the four valence electrons around tin's chemical symbol (Sn) to show tin's electron-dot structure.

EXAMPLE Problem 3 (continued)

3 EVALUATE THE ANSWER

The correct symbol for tin (Sn) has been used, and the rules for drawing electron-dot structures have been correctly applied.

PRACTICE Problems

- 24. Draw electron-dot structures for atoms of the following elements.
 - a. magnesium
- b. thallium
- c. xenon
- 25. An atom of an element has a total of 13 electrons. What is the element, and how many electrons are shown in its electron-dot structure?
- 26. CHALLENGE This element exists in the solid state at room temperature and at normal atmospheric pressure and is found in emerald gemstones. It is known to be one of the following elements: carbon, germanium, sulfur, cesium, beryllium, or argon. Identify the element based on the electron-dot structure at right.

Summary

- The arrangement of electrons in an atom is called the atom's electron configuration.
- Electron configurations are defined by the aufbau principle, the Pauli exclusion principle, and Hund's rule.
- An element's valence electrons determine the chemical properties of the element.
- Electron configurations can be represented using orbital diagrams, electron configuration notation, and electron-dot structures.

Demonstrate Understanding

- 27. Apply the Pauli exclusion principle, the aufbau principle, and Hund's rule to write the electron configuration and draw the orbital diagram for each of the following elements.
 - a. silicon b. fluorine c. calcium d. krypton
- 28. Define valence electron.
- 29. Illustrate and describe the sequence in which ten electrons occupy the five orbitals related to an atom's d sublevel.
- 30. Extend the aufbau sequence through an element that has not yet been identified, but whose atoms would completely fill 7p orbitals. How many electrons would such an atom have? Write its electron configuration using noble-gas notation for the previous noble gas, radon.
- 31. Interpret Scientific Illustrations Which is the correct electron-dot structure for an atom of selenium? Explain.

The Modern Periodic Table

The modern periodic table consists of boxes, each containing an element name, symbol, atomic number, and atomic mass. A typical box from the table is shown in **Figure 3**.

The table orders elements horizontally by the number of protons in an atom's nucleus, and places those with similar chemical properties in columns. The columns are called **groups** or families. The rows are called **periods**.

The periodic table is shown in **Figure 4** on the next page and on the inside back cover of your textbook. Becoming familiar with the periodic table will help you understand how the properties of different elements relate to one another.

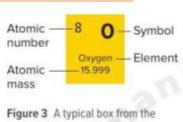

Figure 3 A typical box from the periodic table contains the element's name, its chemical symbol, its atomic number, and its atomic mass.

Groups and periods

Beginning with hydrogen in period 1, there are a total of seven periods. Each group is numbered 1 through 18. For example, period 4 contains potassium and calcium. Oxygen is in group 16. The elements in groups 1, 2, and 13 to 18 possess a wide range of chemical and physical properties. For this reason, they are often referred to as the main group, or representative elements. The elements in groups 3 to 12 are referred to as the transition elements. Elements are also classified as metals, nonmetals, and metalloids.

Metals

Elements that are generally shiny when smooth and clean, solid at room temperature, and good conductors of heat and electricity are called **metals**. Most metals are also malleable and ductile, meaning that they can be pounded into thin sheets and drawn into wires, respectively, as shown in **Figure 5**.

Most representative elements and all transition elements are metals. If you look at boron (B) in column 13, you will see a heavy stairstep line that zigzags down to astatine (At) at the bottom of group 17. This stairstep line is a visual divider between the metals and the nonmetals on the table. In the periodic table shown in **Figure 4** metals are represented by the blue boxes.

Alkali Metals Except for hydrogen, all of the elements on the left side of the table are metals. The group 1 elements (except for hydrogen) are known as the alkali metals. Because they are so reactive, alkali metals usually exist as compounds with other elements. Two familiar alkali metals are sodium (Na), one of the components of salt, and lithium (Li), often used in batteries.

Alkaline Earth Metals The alkaline earth metals are in group 2. They are also highly reactive. Calcium (Ca) and magnesium (Mg), two minerals important for your health, are examples of alkaline earth metals. Because magnesium is strong and relatively light, it is used in applications in which strength and low mass are important, as shown in Figure 6.

Figure 6 Because magnesium is light and strong, it is often used in the production of safety devices such as these caribiners used by climbers.

12	CHM.5.1.01.010.01 Describe the general properties of metals, non-metals and metalloids and their us	Textbook		42	

Transition and Inner Transition Metals The transition elements are divided into transition metals and inner transition metals. The two sets of inner transition metals, known as the lanthanide series and actinide series, are located along the bottom of the periodic table. The rest of the elements in groups 3 to 12 make up the transition metals. Elements from the lanthanide series are used extensively as phosphors, substances that emit light when struck by electrons. Because it is strong and light, the transition metal titanium is used to make frames for bicycles and eyeglasses.

Nonmetals

BIOLOGY Connection Nonmetals occupy the upper-right side of the periodic table. They are represented by the yellow boxes in **Figure 4**. **Nonmetals** are elements that are generally gases or brittle, dull-looking solids. They are poor conductors of heat and electricity. The only nonmetal that is a liquid at room temperature is bromine (Br). The most abundant element in the human body is the nonmetal oxygen, which constitutes 65% of the body mass.

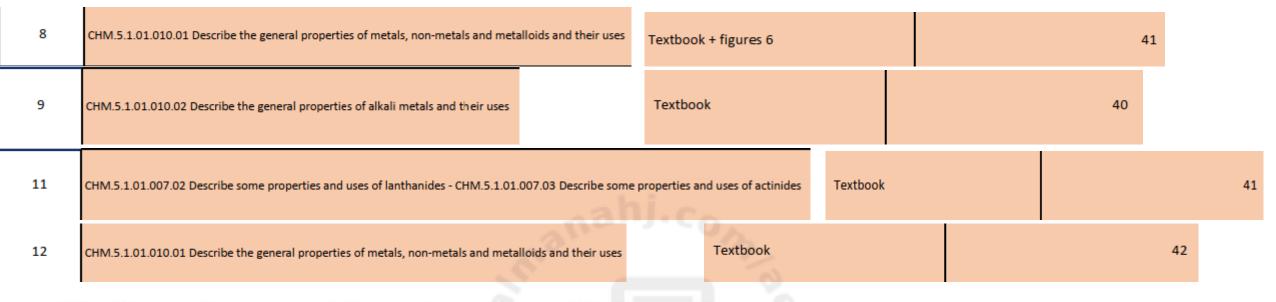

Group 17 comprises highly reactive elements that are known as **halogens**. Like the group 1 and group 2 elements, the halogens are often part of compounds. Compounds made with the halogen fluorine (F) are commonly added to toothpaste and drinking water to prevent tooth decay. The extremely unreactive group 18 elements are commonly called the **noble gases**. They are used in applications where their unreactivity is an advantage, such as in lasers, a variety of light bulbs, and neon signs.

Metalloids

The elements in the green boxes bordering the stairstep line in **Figure 4** are called metalloids, or semimetals.

Metalloids have physical and chemical properties of both metals and nonmetals. Silicon (Si) and germanium (Ge) are two important metalloids used extensively in computer chips and solar cells. Silicon is also used to make prosthetics or in lifelike applications, as shown in Figure 7.

This introduction to the periodic table touches only the surface of its durable explanatory power. You can refer to the Elements Handbook at the end of your textbook to learn more about the elements and their various groups.

13	CHM.5.1.01.004.07 Explain why the properties of the elements in the same group are similar
15	CHM.5.1.01.004.07 Explain why the properties of the elements in the same group are similar

Valence electrons

Recall that electrons in the highest principal energy level of an atom are called valence electrons. Each of the group 1 elements has one valence electron. The group 1 elements have similar chemical properties because they have the same number of valence electrons. This is one of the most important relationships in chemistry: atoms in the same group have similar chemical properties because they have the same number of valence electrons. Each group 1 element has a valence electron configuration of s¹. Each group 2 element has a valence electron configuration of s². Groups 1, 2, and 13 to 18 all have their own valence electron configurations.

Table 3 Electron Configuration for the Group 1 Elements

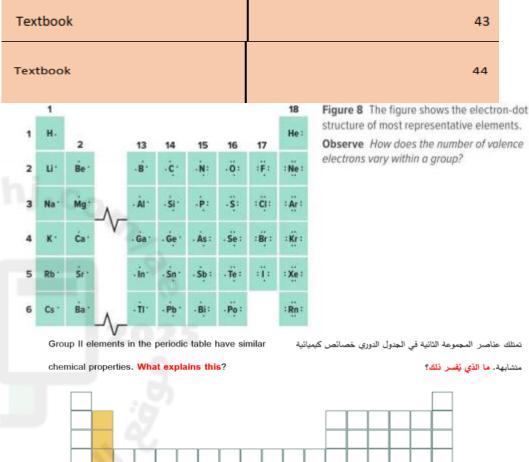

Period 1	hydrogen	1s¹	1s ^t	
Period 2	lithium	1s2s¹	[He]2s ¹	
Period 3	sodium	1s ² 2s ² 2p ⁶ 3s ¹	[Ne]3s1	
Period 4	potassium	1s ² 2s ² 2p ⁶ 3s ² 3p64s ¹	[Ar]4s ¹	

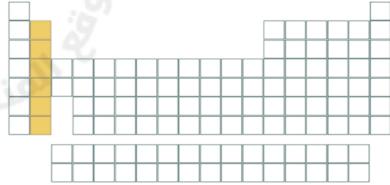

Valence electrons and period

The energy level of an element's valence electrons indicates the period on the periodic table in which it is found. For example, lithium's valence electron is in the second energy level and lithium is found in period 2. Now look at gallium, with its electron configuration of [Ar]4s²3d¹⁰4p¹. Gallium's valence electrons are in the fourth energy level, and gallium is found in the fourth period.

Valence electrons of the representative elements

Elements in group 1 have one valence electron; group 2 elements have two valence electrons. Group 13 elements have three valence electrons, group 14 elements have four, and so on. The noble gases in group 18 each have eight valence electrons, with the exception of helium, which has only two valence electrons. **Figure 8** shows how the electron-dot structures you studied previously illustrate the connection between group number and number of valence electrons. Notice that the number of valence electrons for the elements in groups 13 to 18 is ten less than their group number.

Because they have the same atomic numbers

The s-, p-, d-, and f-Block Elements

The periodic table has columns and rows of varying sizes. The reason behind the table's odd shape becomes clear if it is divided into sections, or blocks, representing the atom's energy sublevel being filled with valence electrons. Because there are four different energy sublevels (s, p, d, and f), the periodic table is divided into four distinct blocks, as shown in **Figure 9** on the next page.

s-Block elements

The s-block consists of groups 1 and 2, and the element helium. Group 1 elements have partially filled s orbitals containing one valence electron and electron configurations ending in s¹. Group 2 elements have completely filled s orbitals containing two valence electrons and electron configurations ending in s². Because s orbitals hold two electrons at most, the s-block spans two groups.

d-Block elements

The d-block contains the transition metals and is the largest of the blocks. With some exceptions, d-block elements are characterized by a filled outermost s orbital of energy level n, and filled or partially filled d orbitals of energy level n-1.

Table 4 Noble Gas Electron Configuration

Period	Principal Energy Level	Element	Electron Configuration
1	n = 1	helium	1s ²
2	n = 2	neon	[He]2s2 ² p ⁶
3	n = 3	argon	[Ne]3s ² 3p ⁶
4	n = 4	krypton	[Ar]4s ² 3d ¹⁰ 4p ⁶

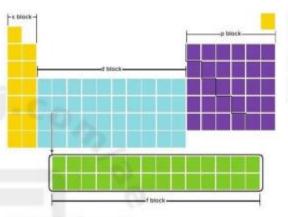

Figure 9 The periodic table is divided into four blocks—s, p, d, and f.

Analyze What is the relationship between the maximum number of electrons an energy sublevel can hold and the number of columns in that block on the diagram?

p-Block elements

After the s sublevel is filled, the valence electrons next occupy the p sublevel. The p-block is comprised of groups 13 through 18 and contains elements with filled or partially filled p orbitals. There are no p-block elements in period 1 because the p sublevel does not exist for the first principal energy level (n=1). The first p-block element is boron (B), which is in the second period. The p-block spans six groups because the three p orbitals can hold a maximum of six electrons.

The group 18 elements, which are called the noble gases, are unique members of the p-block. The atoms of these elements are so stable that they undergo virtually no chemical reactions. The electron configurations of the first four noble gas elements are shown in **Table 4**. Here, both the s and p orbitals corresponding to the period's principal energy level are completely filled. This arrangement of electrons results in an unusually stable atomic structure. Together, the s- and p-blocks comprise the representative elements.

Δ

As you move across a period, electrons fill the d orbitals. For example, scandium (Sc), the first d-block element, has an electron configuration of [Ar] $4s^23d^1$. Titanium (Ti), the next element on the table, has an electron configuration of [Ar] $4s^23d^2$. Note that titanium's filled outermost s orbital has an energy level of n = 4, while the d orbital, which is partially filled, has an energy level of n = 3.

As you learned previously, the aufbau principle states that the 4s orbital has a lower energy level than the 3d orbital. Therefore, the 4s orbital is filled before the 3d orbital. The five d orbitals can hold a total of 10 electrons; thus, the d-block spans 10 groups on the periodic table.

f-Block elements

The f-block contains the inner transition metals. Its elements are characterized by a filled, or partially filled outermost s orbital, and filled or partially filled 4f and 5f orbitals.

The electrons of the f sublevel do not fill their orbitals in a predictable manner. Because there are seven f orbitals holding up to a maximum of 14 electrons, the f-block spans 14 columns of the periodic table.

EXAMPLE Problem 1

ELECTRON CONFIGURATION AND THE PERIODIC TABLE Strontium, which is used to produce red fireworks, has an electron configuration of [Kr]5s². Without using the periodic table, determine the group, period, and block of strontium.

1 ANALYZE THE PROBLEM

You are given the electron configuration of strontium.

Known Unknown

Electron configuration = $[Kr]5s^2$ Group = ?

Period = ?

Block = ?

2 SOLVE FOR THE UNKNOWN

The s² indicates that strontium's valence electrons fill the s sublevel. Thus, strontium is in group 2 of the s-block.

The 5 in 5s² indicates that strontium is in period 5.

For representative elements, the number of valence electrons can indicate the group number.

The number of the highest energy level indicates the period number.

3 EVALUATE THE ANSWER

The relationships between electron configuration and position on the periodic table have been correctly applied.

Atomic Radius

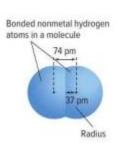

Many properties of the elements tend to change in a predictable way, known as a trend, as you move across a period or down a group. Atomic size is one such periodic trend. The sizes of atoms are influenced by electron configuration.

Recall that the electron cloud surrounding a nucleus does not have a clearly defined edge. The outer limit of an electron cloud is defined as the spherical surface within which there is a 90% probability of finding an electron. However, this surface does not exist in a physical way, as the outer surface of a golf ball does. Atomic size is defined by how closely an atom lies to a neighboring atom. Because the nature of the neighboring atom can vary from one substance to another, the size of the atom itself also tends to vary somewhat from substance to substance.

For metals such as sodium, the atomic radius is defined as half the distance between adjacent nuclei in a crystal of the element, as shown in **Figure 11**. For elements that commonly occur as molecules, such as many nonmetals, the atomic radius is defined as half the distance between nuclei of identical atoms that are chemically bonded together. The atomic radius of a nonmetal diatomic hydrogen molecule (H_{*}) is shown in **Figure 11**.

The radius of a metal atom is one-half the distance between two adjacent atoms in the crystal.

The radius of a nonmetal atom is often determined from a molecule of two identical atoms.

Figure 11 Atomic radii depend on the type of bonds that atoms form.

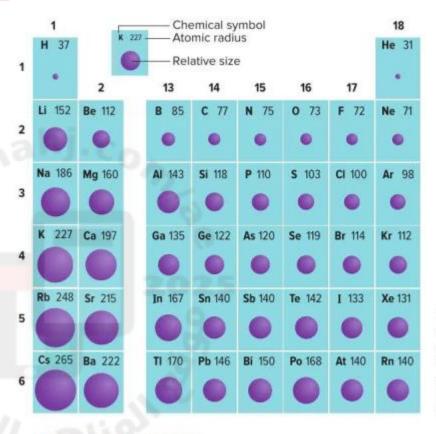

Figure 12 The atomic radii of the representative elements, given in picometers (10⁻¹² m), vary as you move from left to right within a period and down a group.

Infer why the atomic radii increase as you move down a group.

Trends within periods

In general, there is a decrease in atomic radii as you move from left to right across a period. This trend is illustrated in **Figure 12**. It is caused by the increasing positive charge in the nucleus and the fact that the principal energy level within a period remains the same. Each successive element has one additional proton and electron, and each additional electron is added to orbitals corresponding to the same principal energy level. Moving across a period, no additional electrons come between the valence electrons and the nucleus. Thus, the valence electrons are not shielded from the increased nuclear charge, which pulls the outermost electrons closer to the nucleus.

Trends within groups

Atomic radii generally increase as you move down a group on the periodic table. The nuclear charge increases, and electrons are added to orbitals corresponding to successively higher principal energy levels. However, the increased nuclear charge does not pull the outer electrons toward the nucleus to make the atom smaller as you might expect. Why does the increased nuclear charge not make the atom smaller?

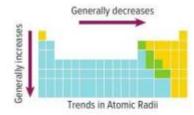

Figure 13 Atomic radii generally decrease from left to right in a period and generally increase as you move down a group.

Moving down a group, the outermost orbital increases in size along with the increasing principal energy level; thus, the atom becomes larger. The larger orbital means that the outer electrons are farther from the nucleus. This increased distance offsets the pull of the increased nuclear charge. Also, as additional orbitals between the nucleus and the outer electrons are occupied, these electrons shield the outer electrons from the nucleus. Figure 13 summarizes the group and period trends.

EXAMPLE Problem 2

ELECTRON CONFIGURATION AND THE PERIODIC TABLE Which has the largest atomic radius: carbon (C), fluorine (F), beryllium (Be), or lithium (Li)? Answer without referring to Figure 12. Explain your answer in terms of trends in atomic radii.

1 ANALYZE THE PROBLEM

You are given four elements. First, determine the groups and periods the elements occupy. Then apply the general trends in atomic radii to determine which has the largest atomic radius.

2 SOLVE FOR THE UNKNOWN

From the periodic table, all the elements are found to be in period 2.

Determine the periods.

Ordering the elements from left-to-right across the period yields: Li, Be, C, and F.

The first element in period 2, lithium, has the largest radius.

Apply the trend of decreasing radii across a period.

3 EVALUATE THE ANSWER

The period trend in atomic radii has been correctly applied. Checking radii values in Figure 12 verifies the answer.

PRACTICE Problems

ADDITIONAL PRACTICE

Answer the following questions using your knowledge of group and period trends in atomic radii. Do not use the atomic radii values in Figure 12 to answer the questions.

- 16. Which has the largest atomic radius: magnesium (Mg), silicon (Si), sulfur (S), or sodium (Na)? The smallest?
- 17. The figure on the right shows helium, krypton, and radon. Which one is krypton? How can you tell?
- 18. Can you determine which of two unknown elements has the larger radius if the only known information is that the atomic number of one of the elements is 20 greater than the other? Explain.

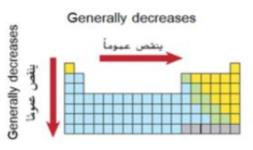

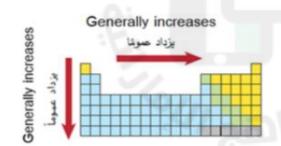

- 19. CHALLENGE Determine which element in each pair has the largest atomic radius:
 - a. the element in period 2, group 1; or the element in period 3, group 18
 - b. the element in period 5, group 2; or the element in period 3, group 16
 - c. the element in period 3, group 14; or the element in period 6, group 15
 - d. the element in period 4, group 18; or the element in period 2, group 16

CHM.5.1.01.009.10 Explain the trend of first ionization energy across a period (Exceptions between Groups 2 & 3 and 5 & 6 are included), and down a group of the periodic table

Textbook + figure 17

Ionization Energy

17

To form a positive ion, an electron must be removed from a neutral atom. This requires energy. The energy is needed to overcome the attraction between the positive charge of the nucleus and the negative charge of the electron.

Ionization energy is defined as the energy required to remove an electron from a gaseous atom. For example, 8.64×10^{-19} J is required to remove an electron from a gaseous lithium atom. The energy required to remove the first outermost electron from an atom is called the first ionization energy. The first ionization energy of lithium equals 8.64×10^{-19} J. The loss of the electron results in the formation of a Li* ion. The first ionization energies of the elements in periods 1 through 5 are plotted on the graph in **Figure 17**.

Removing more than one electron

After removing the first electron from an atom, it is possible to remove additional electrons. The amount of energy required to remove a second electron from a 1+ ion is called the second ionization energy, the amount of energy required to remove a third electron from a 2+ ion is called the third ionization energy, and so on. **Table 5** lists the first through ninth ionization energies for elements in period 2.

Reading across **Table 5** from left to right, you will see that the energy required for each successive ionization always increases. However, the increase in energy does not occur smoothly. Note that for each element there is an ionization for which the required energy increases dramatically. For example, the second ionization energy of lithium (7300 kJ/mol) is much greater than its first ionization energy (520 kJ/mol). This means that a lithium atom is likely to lose its first valence electron but extremely unlikely to lose its second.

Think of ionization energy as an indication of how strongly an atom's nucleus holds onto its valence electrons. A high ionization energy value indicates the atom has a strong hold on its electrons. Atoms with large ionization energy values are less likely to form positive ions. Likewise, a low ionization energy value indicates an atom loses an outer electron easily. Such atoms are likely to form positive ions. Lithium's low ionization energy, for example, is important for its use in lithium-ion computer backup batteries, where the ability to lose electrons easily makes a battery that can quickly provide a large amount of electrical power.

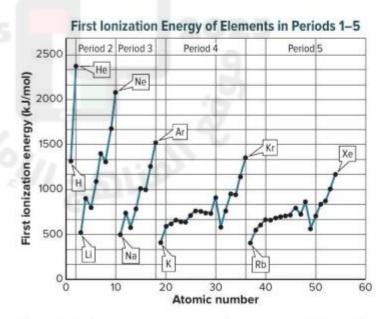

Figure 17 The first ionization energies for elements in periods 1 through 5

Ionic Radius

Atoms can gain or lose one or more electrons to form ions. Because electrons are negatively charged, atoms that gain or lose electrons acquire a net charge. Thus, an **ion** is an atom or a bonded group of atoms that has a positive or negative charge.

You will learn more about ions later, but for now, consider how the formation of an ion affects the size of an atom.

Losing electrons

When atoms lose electrons and form positively charged ions, they always become smaller. The reason is twofold. The electron lost from the atom will almost always be a valence electron. The loss of a valence electron can leave a completely empty outer orbital, which results in a smaller radius. Furthermore, the electrostatic repulsion between the now-fewer number of remaining electrons decreases. As a result, they experience a greater

nuclear charge allowing these remaining electrons to be pulled closer to the positively charged nucleus.

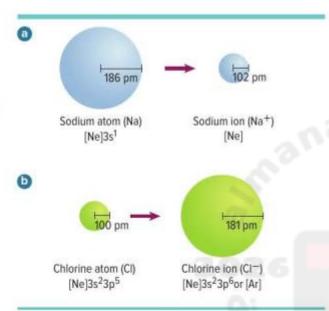

Figure 14 The size of atoms varies greatly when they form ions.

- a. Positive ions are smaller than the neutral atoms from which they form.
- Negative ions are larger than the neutral atoms from which they form.

Gaining electrons

When atoms gain electrons and form negatively charged ions, they become larger. The addition of an electron to an atom increases the electrostatic repulsion between the atom's outer electrons, forcing them to move farther apart. The increased distance between the outer electrons results in a larger radius.

Figure 14b shows how the radius of chlorine increases when chlorine atoms form negative ions. Adding an electron to a chlorine atom increases the electrostatic repulsion among its valence electrons. The increased repulsion causes the electrons to move farther apart and results in the radius of a chloride ion being almost twice as large as that of a chlorine atom.

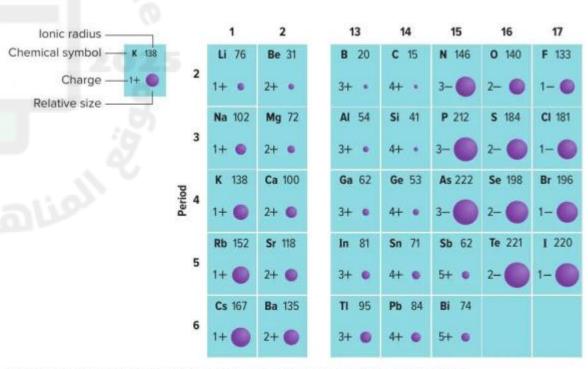

Figure 15 The ionic radii of most of the representative elements are shown in picometers (10⁻¹² m).

Explain why the ionic radii increase for both positive and negative ions as you move down a group.

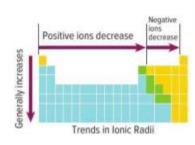

Trends within periods

The ionic radii of most of the representative elements are shown in **Figure 15**. Note that elements on the left side of the table form smaller positive ions, and elements on the right side of the table form larger negative ions.

In general, as you move from left to right across a period, the size of the positive ions gradually decreases. Then, beginning in group 15 or 16, the size of the much-larger negative ions also gradually decreases.

Trends within groups

As you move down a group, an ion's outer electrons are in orbitals corresponding to higher principal energy levels, resulting in a gradual increase in ionic size. Thus, the ionic radii of both positive and negative ions increase as you move down a group. The group and period trends in ionic radii are summarized in Figure 16.

Explain why calcium has a greater atomic radius than magnesium.

Figure 16 The diagram summarizes the general trends in ionic radii.

Which of the following ions has the largest ionic radius?

Electronegativity

The **electronegativity** of an element indicates the relative ability of its atoms to attract electrons in a chemical bond. As shown in **Figure 19**, on the next page, electronegativity generally decreases as you move down a group. **Figure 19** also indicates that electronegativity generally increases as you move from left to right across a period. Fluorine is the most electronegative element, with a value of 3.98, meaning it attracts electrons more strongly than any other element in a chemical bond. Cesium and francium are the least electronegative elements, with values of 0.79 and 0.70, repectively. In a chemical bond, the atom with the greater electronegativity more strongly attracts the bond's electrons. Note that because the noble gases form very few compounds, they do not have electronegativity values.

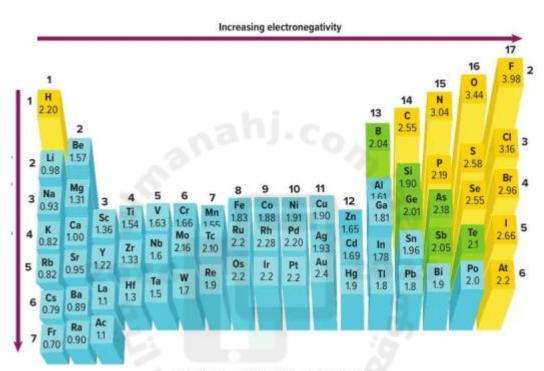

Figure 19 The electronegativity values for most of the elements are shown. The values are given in Paulings, a unit named after American scientist Linus Pauling (1901–1994).

Infer why electronegativity values are not listed for the noble gases.

Valence Electrons and Chemical Bonds

Imagine going on a scuba dive, diving below the ocean's surface and observing the awe-inspiring world below. You might explore the colorful and exotic organisms teeming around a coral reef, such as the one shown in **Figure 1**. The reef is formed from a compound called calcium carbonate, which is just one of thousands of compounds found on Earth. How do so many compounds form from the relatively few elements known to exist? The answer to this question involves the electron structure of atoms and the nature of the forces between atoms.

In previous chapters, you learned that elements within a group on the periodic table have similar properties. Many of these properties depend on the number of valence electrons the atom has. These valence electrons are involved in the formation of chemical bonds between two atoms. A **chemical bond** is the force that holds two atoms together.

Chemical bonds can form by the attraction between the positive nucleus of one atom and the negative electrons of another atom, or by the attraction between positive ions and negative ions. This chapter discusses chemical bonds formed by ions, atoms that have acquired a positive or negative charge. You will learn about bonds that form from the sharing of electrons in a later chapter.

CHM.5.1.02.022.03 Describe how ions (cations and anions) form to fulfill the octet rule

24 CHM.5.1.02.022.05 Write the electron configuration notation, noble gas notation and Lewis structure of different anions and cations

Valence electrons

Recall that an electron-dot structure is a type of diagram used to keep track of valence electrons. Electron-dot structures are especially helpful when used to illustrate the formation of chemical bonds. **Table 1** shows several examples of electron-dot structures. For example, carbon, with an electron configuration of $1s^22s^22p^2$, has four valence electrons in the second energy level. These valence electrons are represented by the four dots around the symbol C in the table.

Table 1 Electron-Dot Structures

Group	1	2	13	14	15	16	17	18
Diagram	Li•	·Be·	٠ġ٠	٠ċ٠	·Ņ·	·o:	:F:	:Ne:

Recall that ionization energy refers to how easily an atom loses an electron. *Electron affinity* (EA) is a term used to describe how much attraction an atom has for electrons. Noble gases, which have high ionization energies and low electron affinities, show a general lack of chemical reactivity. Other elements on the periodic table react with each other, forming numerous compounds. The difference in reactivity is directly related to the valence electrons.

The difference in reactivity involves the octet—the stable arrangement of eight valence electrons in the outer energy level. Unreactive noble gases have electron configurations that have a full outermost energy level. This level is filled with two electrons for helium (1s²) and eight electrons for the other noble gases (ns²np6). Elements tend to react to acquire the stable electron structure of a noble gas.

Positive Ion Formation

Textbook

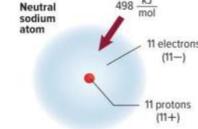

A positive ion forms when an atom loses one or more valence electrons in order to attain a noble gas configuration. A positively charged ion is called a **cation**. To understand the formation of a positive ion, compare the electron configurations of the noble gas neon (atomic number 10) and the alkali metal sodium (atomic number 11).

64

Neon atom (Ne) 1s²2s²2p⁶ Sodium atom (Na) 1s²2s²2p⁶3s¹

Note that the sodium atom has one 3s valence electron; it differs from the noble gas neon by that single valence electron. When sodium loses this outer valence electron, the resulting electron configuration is identical to that of neon.

Figure 2 shows how a sodium atom loses its valence electron to become a sodium cation. By losing an electron, the sodium atom acquires the stable outer electron configuration of neon. It is important to understand that although sodium now has the electron configuration of neon, it is not neon. It is a sodium ion with a single positive charge. The 11 protons that establish the character of sodium still remain within its nucleus.

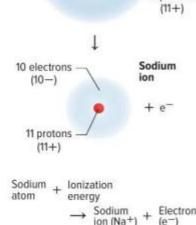

65

Identify the number of electrons in the outermost energy level that are associated with maximum stability.

Metal ions

Metal atoms are reactive because they lose valence electrons easily. The group 1 and 2 metals are the most reactive metals on the periodic table. For example, potassium and magnesium, group 1 and 2 elements, respectively, form K⁺ and Mg²⁺ ions. Some group 13 atoms also form ions. The ions formed by metal atoms in groups 1, 2, and 13 are summarized in Table 2.

25

24 CHM.5.1.02.022.05 Write the electron configuration notation, noble gas notation and Lewis structure of different anions and cations

Transition metal ions

Recall that, in general, transition metals have an outer energy level of ns^2 . Going from left to right across a period, atoms of each element fill an inner d sublevel. When forming positive ions, transition metals commonly lose their two valence electrons, forming 2+ ions. However, it is also possible for d electrons to be lost. Thus, transition metals also commonly form ions of 3+ or greater, depending on the number of d electrons in the electron structure. It is difficult to predict the number of electrons that will be lost. For example, iron (Fe) forms both Fe^{2+} and Fe^{3+} ions. A useful rule of thumb for these metals is that they form ions with a 2+ or a 3+ charge.

Explain in your own words why transition metals can form ions with 2+ or 3+ charges.

Table 2 Group 1, 2, and 13 lons

Group	Configuration	Charge of Ion Formed
1	[noble gas]ns ¹	1+ when the s1 electron is lost
2	[noble gas]ns2	2+ when the s² electrons are lost
13	[noble gas]ns2np1	3+ when the s²p¹ electrons are lost

CHM.5.1.02.022.05 Write the electron configuration notation, noble gas notation and Lewis structure of different anions and cations

Pseudo-noble gas configurations

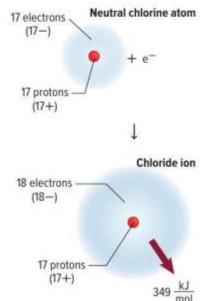

Although the formation of an octet is the most stable electron configuration, other electron configurations can also provide some stability. For example, elements in groups 11–14 lose electrons to form an outer energy level containing full s, p, and d sublevels. These relatively stable electron arrangements are referred to as pseudo-noble gas configurations. The zinc atom has the electron configuration of 1s²2s²2p⁶3s²3p⁶4s²3d¹⁰, in Figure 3. When forming an ion, the zinc atom loses the two 4s electrons in the outer energy level, and the stable configuration of 1s²2s²2p⁶3s²3p⁶3d¹⁰ results in a pseudo-noble gas configuration.

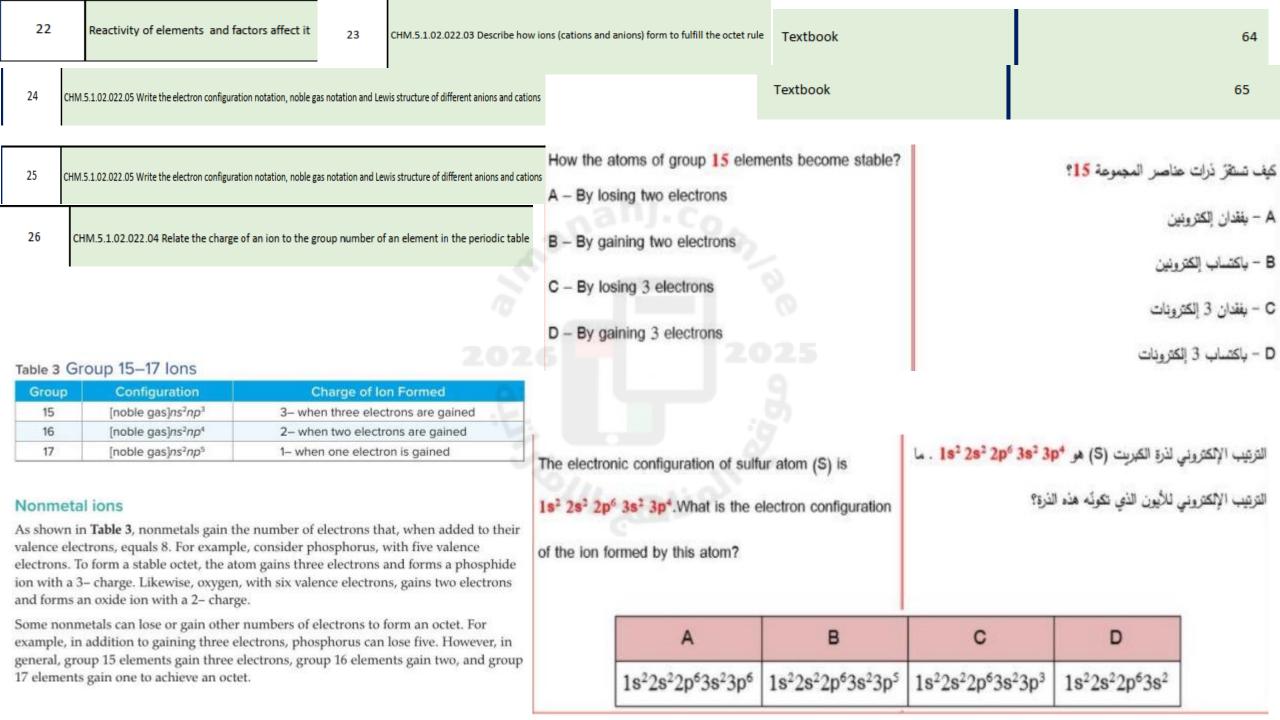

Negative Ion Formation

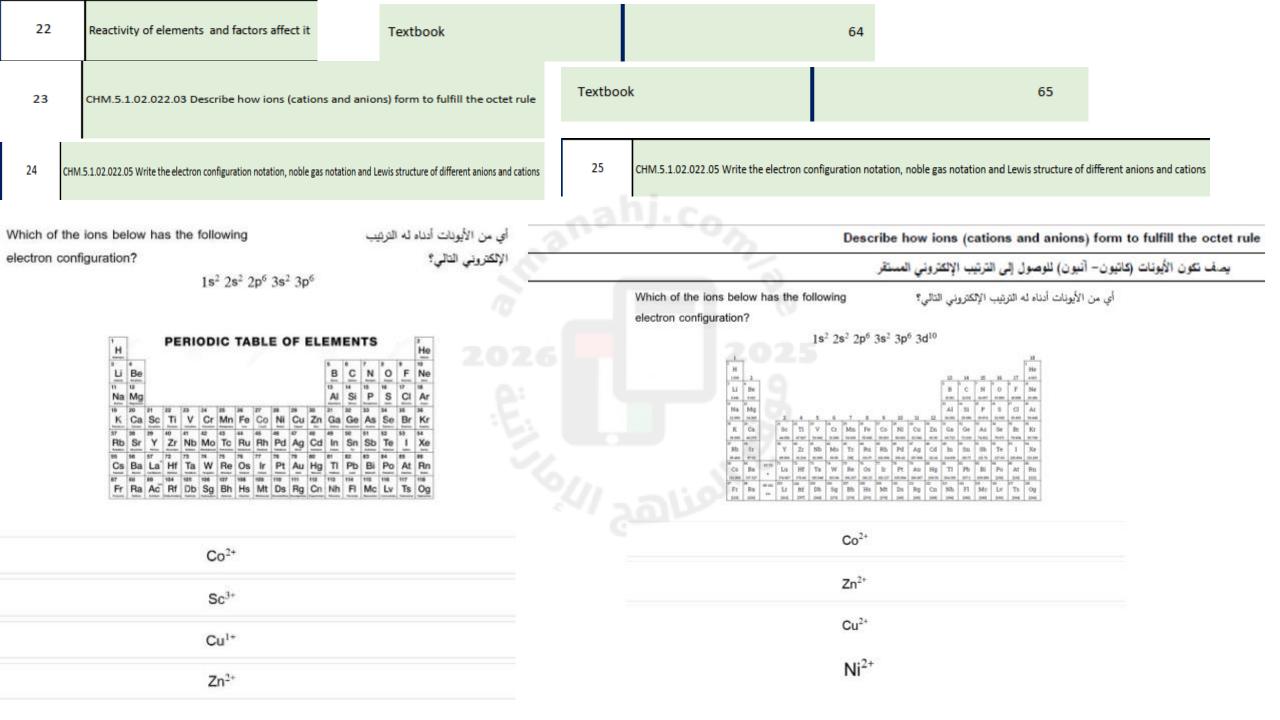

Nonmetals, which are located on the right side of the periodic table, easily gain electrons to attain a stable outer electron configuration. Examine **Figure 4**. To attain a noble-gas configuration, chlorine gains one electron, forming an ion with a 1– charge. After gaining the electron, the chloride ion has the electron configuration of an argon atom.

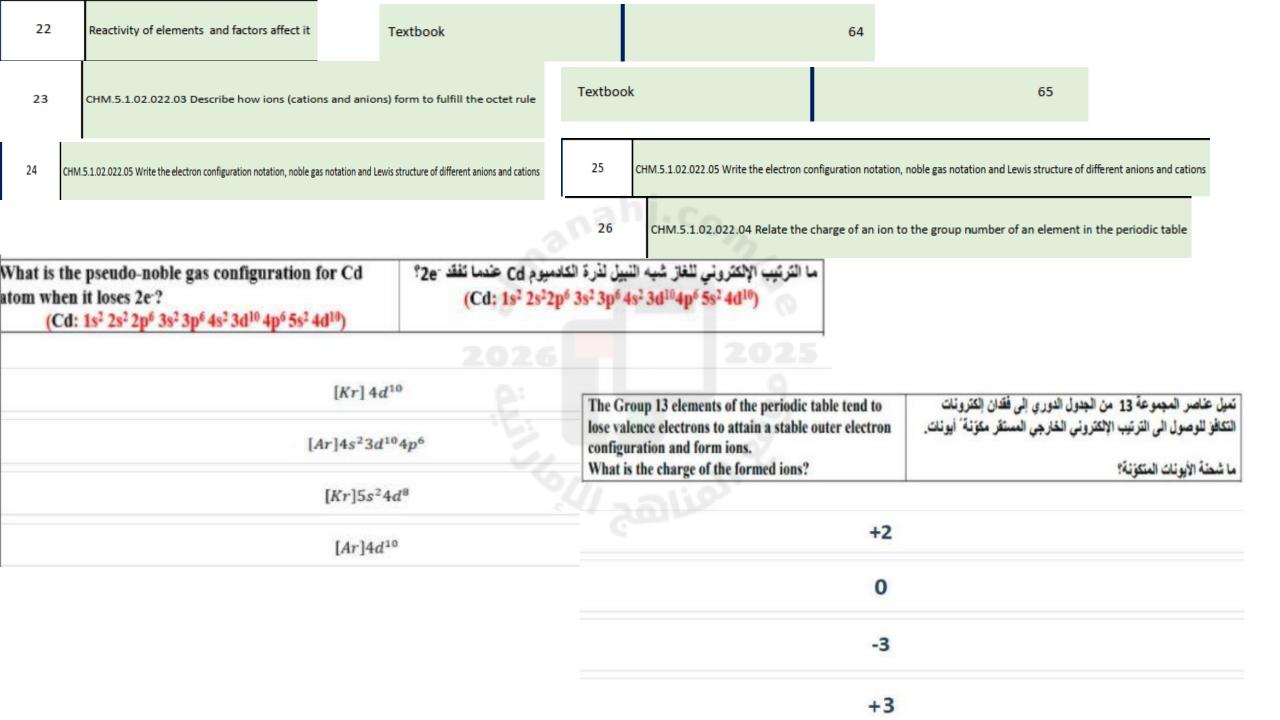

Chlorine atom (Cl) 1s²2s²2p⁶3s²3p⁵
Argon atom (Ar) 1s²2s²2p⁶3s²3p⁶
Chloride ion (Cl⁻) 1s²2s²2p⁶3s²3p⁶

An **anion** is a negatively charged ion. To designate an anion, the ending *-ide* is added to the root name of the element. Thus, a chlorine atom becomes a chloride anion.

Formation of an Ionic Bond

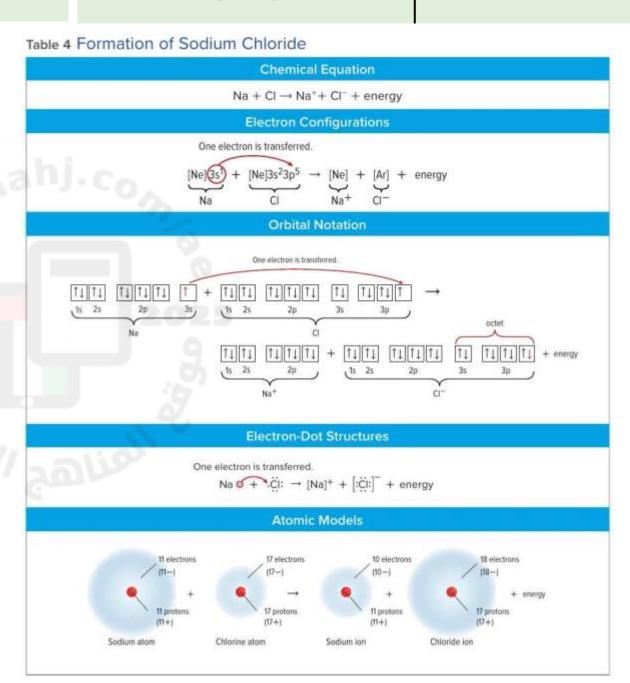

What do the reactions shown in Figure 5 have in common? In both cases, elements react with each other to form a compound. Figure 5a shows the reaction between the elements sodium and chlorine. During this reaction, a sodium atom transfers its valence electron to a chlorine atom and becomes a positive ion. The chlorine atom accepts the electron into its outer energy level and becomes a negative ion. The oppositely charged ions attract each other, forming the compound sodium chloride. The electrostatic force that holds oppositely charged particles together in an ionic compound is referred to as an ionic bond. Compounds that contain ionic bonds are ionic compounds. If ionic bonds occur between metals and the nonmetal oxygen, oxides form. Most other ionic compounds are called salts.

CHM.5.1.02.022.10 Explain how an ionic compound made up of charged particles can be electrically neutral

Binary ionic compounds

Thousands of compounds contain ionic bonds. Many ionic compounds are binary, which means that they contain only two different elements. Binary ionic compounds contain a metallic cation and a nonmetallic anion. Sodium chloride (NaCl) is a binary compound because it contains two different elements, sodium and chlorine. Magnesium oxide (MgO), the reaction product shown in Figure 5b on the previous page, is also a binary ionic compound.

Table 4 summarizes several ways in which the formation of an ionic compound such as sodium chloride can be represented.

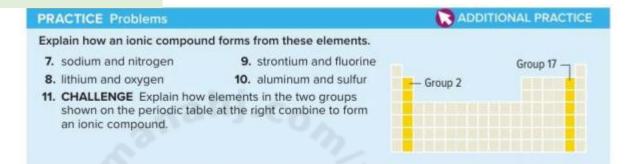

CHM.5.1.02.022.06 Define ionic bond while identifying the type of elements involved and movement of electrons

What role does ionic charge play in the formation of ionic compounds? To answer this question, consider how calcium fluoride forms. Calcium has the electron configuration $[Ar]4s^2$, and needs to lose two electrons to attain the stable configuration of argon. Fluorine has the configuration $[He]2s^22p^5$, and must gain one electron to attain the stable configuration of neon. Because the number of electrons lost and gained must be equal, two fluorine atoms are needed to accept the two electrons lost from the calcium atom. As you can see, the overall charge of one unit of calcium fluoride (CaF_2) is zero.

1 Ca ion
$$\left(\frac{2+}{Ca \cdot ion}\right)$$
 + 2 E ions $\left(\frac{1-}{E \cdot ion}\right)$ = (1) (2+) + (2)(1-) = 0

Next, consider aluminum oxide, the whitish coating that forms on aluminum chairs. To acquire a noble-gas configuration, each aluminum atom loses three electrons and each oxygen atom gains two electrons. Thus, three oxygen atoms are needed to accept the six electrons lost by two aluminum atoms. The neutral compound formed is aluminum oxide (Al_2O_3).

2 Alions
$$\left(\frac{3+}{\text{Alion}}\right)$$
 + 3 O ions $\left(\frac{2-}{\text{O ion}}\right)$ = 2(3+) + 3(2-) = 0

CHM.5.1.02.022.09 Explain the effect of applying an external force on the crystal

Properties of Ionic Compounds

The chemical bonds in a compound determine many of its properties and applications. For ionic compounds, electrical forces in the ionic bonds produce unique physical structures, unlike those of other compounds. The physical structures of ionic compounds also contribute to their bulk physical properties.

Physical structure

In an ionic compound, large numbers of positive ions and negative ions exist together in a ratio determined by the number of electrons transferred from the metal atom to the nonmetal atom. These ions are packed into a regular repeating pattern that balances the forces of attraction and repulsion between the ions.

Examine the pattern of the ions in the sodium chloride crystal shown in Figure 6. Note the highly organized nature of an ionic crystal-the consistent spacing of the ions and the uniform pattern formed by them. Although the ion sizes are not the same, each sodium ion in the crystal is surrounded by six chloride ions, and each chloride ion is surrounded by six sodium ions. What shape would you expect a large crystal of this compound to be? As shown in Figure 6, the one-to-one ratio of sodium and chloride ions produces a highly ordered cubic crystal. As in all ionic compounds, in NaCl, no single unit consisting of only one sodium ion and one chloride ion is formed. Instead, large numbers of sodium ions and chloride ions exist together. If you can, obtain a magnifying lens and use it to examine some crystals of table salt (NaCl). What is the shape of these small salt crystals?

The strong attractions among the positive ions and the negative ions in an ionic compound result in the formation of a crystal lattice. A crystal lattice is a three-dimensional geometric arrangement of particles. In a crystal lattice, each positive ion is surrounded by negative ions, and each negative ion is surrounded by positive ions. Ionic crystals vary in shape due to the sizes and relative numbers of the ions bonded, as shown by the minerals in Figure 7.

Textbook + figure 8

Physical properties

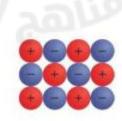

Melting point, boiling point, and hardness are bulk physical properties of matter that are determined by the strength of electrical forces between particles that make up the matter. Because ionic bonds are relatively strong, ionic crystals require a large amount of energy to be broken apart. Thus, ionic crystals have high melting points and high boiling points, as shown in Table 5. Many crystals, including gemstones, have brilliant colors. These colors are due to the presence of transition metals in the crystal lattices.

Table 5 Melting and Boiling Points of Some Ionic Compounds

72

Compound	Melting Point (°C)	Boiling Point (°C)					
Nal	660	1304					
KBr	734	1435					
NaBr	747	1390					
CaCl ₂	782	>1600					
NaCl	801	1413					
MgO	2852	3600					

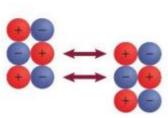

Ionic crystals are also hard, rigid, brittle solids due to the strong attraction between electric charges that holds the ions in place. When an external force is applied to the crystal-a force strong enough to overcome the attractive forces holding the ions in position within the crystal-the crystal cracks or breaks apart, as shown in Figure 8. The crystal breaks apart because the applied force repositions the like-charged ions next to each other; the resulting repulsion between electric forces breaks apart the crystal.

Undisturbed ionic crystal Before the force is applied, the crystal has a uniform pattern of ions.

Applied force realigns particles. If the applied force is strong enough, it pushes the ions out of alignment,

Forces of repulsion break crystal apart. A repulsive force created by nearby like-charged ions breaks apart the crystal.

Figure 8 Strong attractive forces hold the ions in place until a force strong enough to overcome the attraction is applied.
